Chapter 1

Introduction

1.1 Problem description

Due to the pandemic, the last two years kept us at home, and we were tempted to use the Internet more often. Recent statistics of the monthly in-home data usage in the United States from January to March 2020 showed a drastic increase compared to the years before [53]. Even Europol (an agency that fights against terrorism, cybercrime, and other threats [21]) rose awareness of new cyber threats related to an increase of misinformation. As stated in their yearly Internet Organised Crime Threat Assessment (IOCTA), citizens and businesses are looking for any kind of information that is desperately needed. Both contributes to cybercriminal acts. [20]

The increase of cyberattacks is merely connected to the pandemic, also fast growing technology comes along with new security concerns. Especially in cloud computing due to access to large pools of data and computational resources, controlling access to services is becoming a tougher challenge nowadays. Besides traditional security leverages such as firewalls or intrusion detection systems, one known methodology to strengthen infrastructures is to learn from those who attacks it. Honeypots are a security resource whose value lies in being probed, attacked, or compromised [52]. By getting attacked from others, zero-day-exploits, worm activity, or bots can be detected. In retrospect, this helps to adapt, or fix infrastructures before more damage occurs. As a cloud provider, it is a crucial point if and how attacks on production server could have been prevented. Considering the Global Security Report by Trustwave, the amount of attacks doubled in 2019, and increased by 20% in 2020 [9]. It puts cloud providers to the third most targeted environments for cyber attacks. Corporate and internal networks are on top of this ranking. However, this rise of attacks on cloud infrastructures has shown the importance why more security will be necessary in the future. Thus, making it a thrilling challenge for the upcoming years.

1.2 Justification, motivation and benefits

1.3 Research questions

The following research questions have been answered in this thesis:

1. How can honeypots contribute to a more secure cloud environment including baiting adversaries to our honeypots, and controlling their requests?
2. What is a preferable way to handle data management and visualization?
3. How can we analyze our data to get more information?

1.4 Limitations

Heidelberg offers a cloud service, called “HeiCloud”. Since we tailor our implementation for this service. Moreover, it exists a vast variety of different honeypots which bound us to a very few of them.

Chapter 2

Background

Using honeypots in a cloud environment merge two varying principals together. This chapter concludes the fundamental knowledge that is needed to comprehend the upcoming experiments. If the reader has a profoundly understanding of cloud computing, honeypots, and virtualization he can skip this chapter.

2.1 Virtualization

Virtualization, often referred to virtual machine (VM), is defined by Kreuter [34] as “an abstraction layer or environment between hardware component and the end-user”. A VM runs on top of an operating system (OS) core components. By an abstraction layer, the virtual machine is connected with the real machine by hypervisors or virtual machine monitors (VMM). Hypervisors can use real machine hardware components, but also support virtual machine operating systems and configurations. Both are similar to emulators, that are defined by HA [25] as “process whereby one computer is set up to permit the execution of programs written for another computer”. This allows to management multiple VM with real machine resources. There are three different types of virtualization, (i) software virtual machines, (ii) hardware virtual machines, and (iii) virtual OS/containers. Software virtual machine’s manage interactions between the host operating system and guest operating system. Hardware virtual machine’s offers direct and fast access to the underlying resources. It uses hypervisors, modified code, or APIs. Virtual OS/container partitions the host operating system into containers or zones. [18]

2.2 Cloud Computing

Nowadays it is one of the well-known keywords and has been used by vary large companies such as Google, or Amazon, however, the term “cloud computing” dates back to the late 1996, when a small group of technology executives of Compaq Computer framed new business ideas around the Internet.[43] Starting from 2007 cloud

computing evolved into a serious competitor and outnumbered the keywords “virtualization”, and “grid computing” reported by Google trends [59]. Shortly, various cloud provider become publicly available, each with their own strengths and weaknesses. For example IBM’s Cloud¹, Amazon Web Services², and Google Cloud³. Why are clouds so attractive in practice?

- It offers major advantages in terms of cost and reliability. When demand is needed, consumers do not have to invest in hardware when launching new services. Pay-as-you-go allows flexibility.
- Consumer can easily scale with demand. When more computational resources are required due to more requests, scaling up instances in conjunction with a suited price model are straightforward.
- Geographically distributed capabilities supply the need for world-wide scattered services.

2.2.1 Definition of Cloud Computing

Considering the definition of Brian Hayes, cloud computing is “a shift in the geography of computation” [26]. Thus, computational workload is moved away from local instances towards services and datacenters that provide the need of users [11].

Considering the definition of the National Institute of Standards and Technology (NIST), cloud computing “is a model for enabling ubiquitous, convenient, on-demand network access to a shared pool of configurable computing resources (e.g., networks, servers, storage, applications, and services) that can be rapidly provisioned and released with minimal management effort or service provider interaction” [35]. NIST not only reflects the geographical shift of resources such as datacenters, but also mentions on-demand usage that contributes to a flexible resource management. Moreover, NIST composes the term in five essential characteristics, three service models (see subsection 2.2.2), and four deployment models (see subsection 2.2.3) [35]

On-demand-self-service refers to the unilaterally provision computing capabilities. Consumers can acquire server time and network storage on demand without a human interaction.

Broad network access characterizes the access of capabilities of the network through standard protocols such as Hypertext Transfer Protocol (HTTP). Heterogeneous thin and thick client platforms should be supported.

Resource pooling allows the provider’s computing resources to be pooled across several consumers. A multi-tenant model with different physical and virtual resources

¹<https://www.ibm.com/cloud>

²<https://aws.amazon.com/>

³<https://cloud.google.com/>

are assigned on demand. Other aspects such as location are independent and cannot be controlled on a low-level by consumers. Moreover, high-level access to specify continent, state, or datacenter can be available.

Rapid elasticity offers consumers to extend and release capabilities easily. Further automization to quickly increase resources when demand skyrockets significantly can be supported regardless limit and quantity at any time.

Measured service handles resources in an automated and optimized manner. It uses additional metering capabilities to trace storage, processing, bandwidth, and active user accounts. This helps to monitor, and control resource usage. Thus, contributing to transparency between provider and consumer.

2.2.2 Service models

Service models are categorized by NIST into three basic models based on usage and abstraction level. Figure 2.1 shows the connection between each model whereas cloud resource are defined in subsection 2.2.3. Due to vast range of functionalities, Infrastructure-as-a-Service (IaaS) builds the foundation of service models. Each model on top represents a user-friendly abstraction with derated capabilities. Table 2.1 shows examples of such service models.

Figure 2.1: Abstract visualization of service models. The lowest level within the container “cloud resources” represents the depth of functionalities. Therefore, Infrastructure-as-a-Service (IaaS) offers the most functionalities whereas the others have a user-friendly abstraction.

Software-as-a-Service (SaaS) is a high-level abstraction to consumers. Controlling the underlying infrastructure is not supported. Often provider uses a multi-tenancy system architecture to organize each consumer’s application in a separate environment. It helps to employ scaling with respect to speed, security availability, disaster recovery, and maintenance. Main objective of SaaS is to host consumer’s software or

application that can be accessed over the Internet using either a thin or rich client. [19] “Limited user-specific application configuration settings” can be made [35].

Platform-as-a-Service (PaaS) pivots on the full “Software Lifecycle” of an application whereas SaaS distincts on hosting complete applications. PaaS offers ongoing development and includes programming environment, tools, configuration management, and other services. In addition, the underlying infrastructure is not managed by the consumer. [35]

Infrastructure-as-a-Service (IaaS) offers a low-level abstraction to consumers with the ability to run arbitrary software regardless of operating system or application. In contrast to SaaS, IT infrastructures capabilities (such as storage, networks) can be used. It strongly depends on virtualization due to integration, or decomposition of physical resources. [35]

Data-as-a-Service (DaaS) serves as a virtualized data storage service on demand. Motivations behind such services could be upfront costs of on-premise enterprise database systems. [19] Mostly they require “dedicated server, software license, post-delivery services, and in-house IT maintenance” [19] Whereas DaaS costs solely what consumer’s need. When dealing with a tremendous amount of data, file systems and RDBMS often lack in performance. DaaS outruns such weak links by employing a table-style abstraction that can be scaled.[19]

Hardware-as-a-Service (HaaS) offers IT hardware, or datacenters to buy as a pay-as-you-go subscription service. The term dates back to 2006 during a time when hardware virtualization became more powerful. It is flexible, scalable and manageable.[59]

Table 2.1: Providers of cloud service models

SaaS	PaaS	IaaS	Daas	HaaS
Google Mail	Google App	HeiCloud	Adobe Buz-	Amazon EC2
Google Docs	Engine		zword	
	Windows	Amazon EC2	ElasticDrive	Nimbus
Microsoft	Azure			
Drive	AWS Elastic		Google Big	Enomalism
	Beanstalk		Table	
			Amazon S3	Eucalyptus
			Apache	
			HBase	

2.2.3 Deployment models

Deployment models are categorized by NIST into four basic models. Each differs in data privacy, location, and manageability [35]. Table 2.2 shows examples of such deployment models.

Table 2.2: Examples for cloud deployment models

Private Cloud	Community Cloud	Hybrid Cloud	Public Cloud
Seafire	Seafire	IBM Cloud	Amazon EC2
Nextcloud	Nextcloud	Amazon EC2	Google AppEngine

Private clouds offer the highest level of control in regard of data privacy, and utilization. Mostly, such clouds are deployed within in a single organization, either managed by in-house teams or third party suppliers. In addition, it can be on or off premise. Within private clouds consumers have full control of their data. Especially for European data privacy laws, it is not negligible when data is stored abroad and thus under law of foreign countries. However, the popularity has not been withdrawn due to immense costs when moving towards public clouds. [19, 35]

Community clouds can be seen as a conglomerate of mutliple organizations that merge their infrastructure with respect to a commonly defined policy, terms, and condition beforehand. [35]

Public clouds represents the most used deployment models. In contradiction to private one, public clouds are fully owned by the service provider such as business, academics, or government organization. Consumers do not know where their data is distributed. In addition, contracts underlie custom policies. [35]

Hybrid cloud is a mixture of two or more cloud infrastructures, such as private and public cloud. However, each entity keeps its core element. Hybrid clouds defines “standardized or proprietary technology to enables data and application portability”[35].

2.3 Honeypots

The term “honeypot” exists since more than a decade. 1997 was the first time that a free honeypot solution became public. Deception Toolkit (DTK), developed by Fred Cohen, released the first honeypot solution. However, the earliest drafts of honeypots are from 1990/91, and built the foundation for Fred Cohen’s DTK. Clifford Stoll’s book “The Cuckoo’s Egg”[54], and Bill Cheswick’s whitepaper “An Evening With Berferd”[15] describe concepts that are consider nowadays as honeypots.[52]

A honeypot itself is a security instrument that collects information on buzzing attacks. It disguises itself as a system, or application with weaklinks, so that it gets exploited and gathers knowledge about the adversary. In 2002 a Solaris honeypot helped to detect an unknown dtspcd exploit. Interestingly, a year before in 2001 the Coordination Center of Computer Emergency Response Team (CERT), “an expert group that handles computer security incidents”[23], shared their concerns regarding the dtspcd. Communities were aware that the service could be exploited to get access and remotely compromise any Unix system. However, during this time such an exploit was not known, and experts did not expect any in the near future. Gladly, early instances based on honeypot technologies could detect new exploits and avoid further incidents. Such events lay emphasis on the importance of honeypots.

2.3.1 Definition of a Honeypot

Dozen of definitions for honeypots circulate through the web that causes confusion, and misunderstandings. In general, the objective of a honeypot is to gather information about attacks, or attack patterns [37]. Thus, contributing as an additional source of security measure. See subsection 2.3.3 for a detailed view regarding honeypots in the security concept. As Spitzner [52] has listed, most misleading definitions are: honeypot is a tool for deception, it is a weapon to lure adversaries, or a part of an intrusion detection system. In order to get a basic understanding, we want to exhibit some of the key definitions. Spitzner [52] defines honeypots as a “security resource whose value lies in being probed, attacked, or compromised”. Independent of its source (e.g. server, application, or router), we expect that our instance is getting probed, attacked, and eventually exploited. If a honeypot does not match this behaviour, it will not provide any value. It is important to mention that honeypots do not have any production value, thus, any communication that is acquired is suspicious by nature [52]. In addition, Spitzner [52] points out that honeypots are not bounded to solve a single problem, hence, they function as a generic perimeter, and fit into different situation. Such functions are attack detection, capturing automated attacks, or alert/warning generator. Figure 2.2 show an example how honeypots could be used in an IT infrastructure.

In general, we differentiate two types of honeypots (i) Production honeypots (ii) Research honeypots. This categorization has their origin from Mark Rosch developer of Snort during his work at GTE Internetworking.

Production honeypots are the common type of honeypots everyone would think of it. The objective is to protect production environments, and to mitigate the risk of attacks. Normally, production honeypots are easy to deploy within an organization. Mostly, low-interaction honeypots are chosen due to a significant reduce in risk. Thus, adversaries might not be able to exploit honeypots to attack other systems. Downside is a lack of information. Standard information like the origin of attacks, or what exploits are used can be collected, whereas insides about communication of

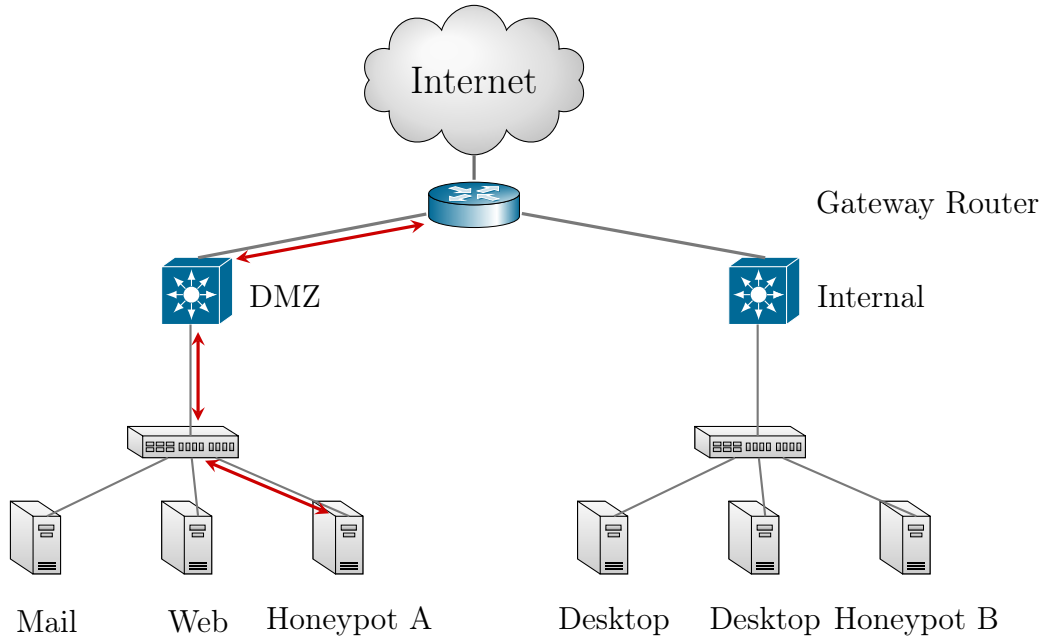

Figure 2.2: Example of honeypots in a simplified network (derived from [52]). Each of the demilitarized zone, and internal network are separated by a router and a Layer-3 switch. As derived from above, in each network a honeypot is available (honeypot A, B). The read path symbolises the path of an attacker coming from the gateway router.

attackers, or deployment of such attacks are unlikely to obtain. In contrast, research honeypots do fulfill this objective.[52]

Research honeypots are used to learn more in detail about attacks. The objective is to collect information about the clandestine organizations, new tools for attacks, or the origin of attacks. Research honeypots are unlikely for production environments due to a higher increase of risk. Facing an increase in deployment complexity, and maintenance does not attract a production usage.[52]

It is worth to mention that there is no exact line between research or production honeypots. A possible cases are honeypots that could function as either an production or an research honeypot. Due to their dynamic range in which they are applicable it makes it hard to distinguish.

Provos [42] adds an additional differentiation for the virtual honeypot framework and splits it into the following types:

- Physical honeypots are “real machines on the network with its own IP address” [42]

- Virtual honeypots are “simulated by another machine that responds to network traffix sent to the virtual honeypot” [42]

2.3.2 Level of Interaction

When building and deploying a honeypot, the depth of information has to be defined beforehand. Should it gather unauthorized activities, such as an NMAP scan? Do you want to learn about buzzing tools and tactics? Each depth brings a different level of interaction because some information depends on more actions of adversaries. Therefore, honeypots differ in level of interaction.

Low-interaction honeypots provide the lowest level of interaction between an attacker and a system. Only a small set of services like SSH, Telnet, or FTP are supported which contributes to the deployment time. In terms of risk, a low-interaction honeypot does not give access to the underlying OS which makes it safe to use in a production environment. For example using an SSH honeypot, such services are emulated, thus, attackers can attempt to login by brute force or by guessing, and execute commands. However, the adversary will never gain more access because it is not a real OS. However, safety comes with the downside of less information. Collected is limited for statistical purpose such as (i) Time and data of attack (ii) Source IP address and source port of the attack (iii) Destination IP address and destination port of the attack. Transactional information can not be collected. [52]

A medium-interaction honeypot offers more sophisticated services with higher level of interaction. It is capable to respond to certain activities. For example a Microsoft IIS Web server honeypot could be able to respond in a way that a worm is expecting it. The worm would get emulated answers, and could be able to interact with it more in detail. Thus, gathering more severe information about the attack, including privilege assessment, toolkit capturing, and command execution. In contrast, medium-interaction honeypots allocate more time to install and configure. In addition, more security checks have to be performed due to a higher interaction level than low-interaction honeypots. [52]

High-interaction honeypots are the highest level interaction. Mostly, they represent a real OS to provide a full set of interactions to attackers. They are so powerful because other production servers do not differ much to high-interaction honeypots. They represent real systems in a controlled environment. Obviously, the amount of information is tremendous. It helps to learn about (i) new tools (ii) finding new bugs in the OS (iii) the blackhat community. However, the risk of such a honeypot is extremely high. It needs severe deployment and maintenance processes. Therefore, it is time consuming.

2.3.3 Security concepts

Security concepts are classified by Schneier [50] in prevention, detection, and reaction. Prevention includes any process that (i) discourages intruders and (ii) hardens systems to avoid any kind of breaches. Detection scrutinize the identification of attacks that threatens the systems (i) confidentiality (ii) integrity and (iii) availability. Reaction treats the active part of the security concept. When attacks are detected, it conducts reactive measures to remove the threat. Each part is designed to be sophisticated so that all of them contribute to a secure environment. [37]

Honeypots contribute to the security concept like firewalls, or Intrusion Detection Systems (IDS). Regarding prevention, honeypots add only a small value because security breaches cannot be identified. Moreover, attackers would avoid wasting time on honeypots and go straight for production systems instead.

However, detection is one of the strengths of honeypots. Attacks often vanish in the sheer quantity of production activities. If any connection is obtained to a honeypot it is suspicious by nature. In conjunction with an alerting tool, attacks can be detected.

Honeypots strongly supply reaction tools due to their clear data. In production environments, finding attacks for further data analysis are not easy to grasp. Often data submerge with other activities which complicates the process of reaction. [37] Nawrocki et al. [37] distinct honeypots from other objectives such as firewall, or log-monitoring.

Table 2.3: Distinction between security concepts based on areas of operations (derived from [37]).

Objective	Prevention	Detection	Reaction
Honeypot	+	++	+++
Firewall	+++	++	+
Intrusion Detection Sys.	+	+++	+
Intrusion Prevention Sys.	++	+++	++
Anti-Virus	++	++	++
Log-Monitoring	+	++	+
Cyber Security Standard	+++	+	+

2.3.4 Value of Honeypots

To assess the value of honeypots we want to take a closer look to their advantages and disadvantages.[36, 30, 52]

Advantages

- **Data Value:** Collected data is often immaculate and does not contain noise from other activities. Thus, reducing the total size of data, and speed up the analyzation.
- **Resources:** Firewalls, and IDS are often overwhelmed by the gigabits of traffic, thus, dropping network packets for analyzation. This results in a far less effective detection for malicious network activities. However, honeypots are independent of resources because they only capture their activities at itself. Due to resource limitation, expensive hardware is not needed.
- **Simplicity:** A honeypot do not require any complex algorithms, or databases. It should be able to quickly deploy it somewhere. Research honeypots might come with a certain increase of complexity. However, if a honeypot is complex, it will lead to misconfigurations, breakdowns, and failures.
- **Return on Investment:** Capturing attacks immediately informs users that attacks occur on the infrastructure. This helps to demonstrate their value, and contributes to new investment in other security measurements.

In addition, Nawrocki et al. [37] listed four more advantages of honeypots:

- **Independent from Workload:** Honeypots only process traffic that is direct to them.
- **Zero-Day-Exploit Detection:** It helps to detect unknown strategies and zero-day-exploits.
- **Flexibility:** Well-adjusted honeypots for a variety of specific tasks are available.
- **Reduced False Positives and Negatives:** Any traffic or connection to a honeypot is suspicious. Client-honeypots verify such attacks based on system state changes. This results in either false positive, or false positive.

Disadvantages

- **Narrow Field of View:** Only direct attacks on honeypots can be investigated whereas attacks on production system are not detect by it.
- **Fingerprinting:** A honeypot often has a certain fingerprint that can be identified by attackers. Especially commercial ones can be detected by their responses or behaviours.
- **Risk to the Environment:** Using honeypots in an environment always increase the risk. However, it depends on the level of interaction.

2.3.5 Honeynets

Instead of having single honeypots that can be attacked, a honeynet offers a complete network of standard production systems such as you would find in an organization. Those systems are high-interaction honeypots, thus, allowing to fully interact with the OS, and applications. Key idea is that an adversary can probe, attack, and exploit these systems so that we can derive interaction within this network. It should be noticed that a honeynet have to be protected by firewall. Figure 2.3 represents such a honeynet within an organization.

Figure 2.3: Example of honeynets in a simplified network (derived from [52]). On the left, this network presents the honeynet consisting of several other honeypots. On the right the network presents an ordinary subnet consisting of mail, web, and FTP server.

In comparison to regular honeypot, the greatest value of honeynets is the usage of true production systems. Black hats often do not know that they attack a honeynet, thus, adding value to prevention. However, the downsides are high complexity and maintenance that is needed to keep a honeynet running. [52]

2.3.6 Legal Issues

Considering questions related to legal issues of honeypots can easily exceed this thesis. In this regard, we restrict us to the country we reside in, so that, we are only

concerned about the European Union (EU) regulations, EU directives, and international agreements. Honeypots collect (i) content data that is used for communication, and (ii) transactional data that is used to establish the connection. Sokol et al. [51] studied the legal conditions for data collection and data retention. They come to the conclusion that administrators of honeypots have a legal ground of legitimate interest to store and process personal data, such as IP addresses. Moreover, for production honeypots the legitimate interest is to secure services. Regarding the length of data retention, the principle of data minimization has to be considered which means there is no clear answer for it. Any published data of research honeypots needs to be anonymized.

2.4 Related Work

The Snort [14] inline extension *Bait'n'Switch* [10] redirects attackers from production systems to honeypots. Usually Snort drops malicious packets when they are detected, and creates a specific rule to block malicious activity from the source. In contrast, *Bait'n'Switch* does not create a rule to block more request, instead it redirects them to honeypots. The attacker does not realize that all packets are rerouted, and that the original target has changed. The IDS is bounded to its signature database and can only redirect known attacks. [39]

Whereas *Bait'n'Switch* had to drop the first attack which leads to a suspicious behaviour for attackers, the *Intrusion Trap System* [55] is capable of forwarding the first request. Therefore, the first recognized attack by the IDS can be forwarded and answered by honeypots. [39]

The *honeyd* [42] extension *Honeycomb* [33] enables automatically generates *Snort* and *Bro* [40] signatures for all incoming traffic. In addition, new signatures are created for similar patterns if they do not exist already, and updating of existing ones to improve their quality. This is based on the incoming traffic, and the corresponding attack session. Even mutations of attacks are considered. It generates a more generic description for signatures in order to match the original attack, and the mutation. It helps to keep the size of signatures small. However, the downside of this extension is the missing verification of attacks. Wrongly redirected traffic will not be proven if an attack was successful even though a signature has been created. [39]

Chapter 3

Cloud Security with Honeypots

In this chapter we investigate... tbc. In section 3.3, Results, we show various results of honeypots in heiCLOUD, stress out the importance of it, and lay emphasis on our concept in chapter 4.

3.1 Introduction

As previously mention in section 2.2, Cloud Computing, using cloud resources are becoming the go-to option for new services, and applications. Kelly et al. [31] thoroughly investigated honeypots on cloud providers such as Azure, AWS, or Goolge Cloud Platform. Followingly, we present their results that we want to compare with the results of HeiCLOUD later on. The results are collected by T-Pot version 20.06.0. over a duration of 3 weeks. A detailed description of T-Pot is done in subsection 3.2.2, T-Pot. In addition, Kelly et al. [31] considered different server geographical locations. They have collected data from East US, West Europe, Southeast Asia. Table 3.1 shows the results presented by Kelly et al. [31]. Dionaea, Cowire, and Conpot are the most attacked honeypots in comparison to the others. Regarding Amazon Web Services (AWS), Dionaea account 91% of the total attacks, Glutton and Cowire are minor with 5%, and 2%. Interestingly, Cowire reported several attacks related to the COVID-19 pandemic to enable social engineering methods. In contrast to AWS, Cowire logged the majority of attacks with 51% on Google Cloud (GCP). Beside several automated attacks trying to login with default credentials, adversaries tried to gather information about CPU architecture, scheduled tasks, and privilege escalation. Microsoft Azure reflects nearly the same results as the other two cloud providers beforehand.

The overall results show an average ratio of 55.000 attacks per day, summing up to roughly 1.6 mio in total. Similar results for different regions could have been reproceded. Their results clearly show the disparty of the regions Europe, US, and Asia. An important question that Kelly et al. [31] answered is if attackers target services on cloud providers based on the cloud providers' market share. They could not confirm this assumption based on the fact that Google Cloud with the smallest

Table 3.1: Overview of attacks on cloud providers. For a better overview, only the three most attacked honeypots are listed. The others combine several honeypots.

Provider	Honeypot				In Total
	Dionaea	Cowire	Glutton	others	
Amazon Web Services	228.075	4.503	11.878	3.688	248.144
Google Cloud	162.570	297.818	84.375	36.403	581.116
Microsoft Azure	308.102	9.012	17.256	6.365	340.735

market share received most of the attacks. In total, the most of the attacks are originated from Vietnam, Russia, United States, and China. Due to technologies such as VPN, or Tor, the geolocation only indicates the last node, so location data might be distorted. Across all providers roughly 80% of the source IP addresses had a bad reputation and could be filtered by the organization. The operating devices used for attacking the services are mostly Windows 7 or 8, and different Linux kernels and distros. Windows devices target vulnerabilities in remote desktop sharing software. Such vulnerabilities are (i) CVE-2006-2369[3] (RealVNC) in the US region, (ii) CVE-2001-0540[1] (RDP) in EU and Asia regions, (iii) CVE-2012-0152[4] (RDP) in the Asia region, and (iv) CVE-2005-4050[2] (VoIP) in EU region. In addition, attackers were also capable of disguising any fingerprinting activity of p0f.

In this chapter, we want to compare the findings Kelly et al. [31] claimed in the paper “A Comparative Analysis of Honeypots on Different Cloud Platforms” with ours using the University Heidelberg’s cloud solution. First, a short introduction of heiCLOUD is held, followed by a closer lookup of T-Pot that is used to acquire data. Lastly, we present the results and do a thorough comparison.

3.2 Methodology

3.2.1 Cloud Provider

University Computing Center Heidelberg [57] offers a “IaaS specially tailored for higher education and research institutions” called heiCLOUD. It supplies multiple institutes at University Heidelberg with storage, virtual machines, or network components. In addition, heiCLOUD is a DFN¹ member, and offers others to use their services. As stated on their information website[56], it is (i) capable of freely manageable IT resources, (ii) beholds a stable and fast connection, (iii) ensures high availability and scalability, (iv) has freely selectable VM operating systems, and

¹German National Research and Education Network, the communications network for Science and research in Germany

(v) has a transparent payment model [56]. Based on the open source application OpenStack, users can easily create own network areas, and manage their space individually. Unlike well-known cloud providers, heiCLOUD servers are located withing Germany, thus, abide by the European data privacy law. HeiCLOUD have never considered honeypots for additional cyber security measurements.

3.2.2 T-Pot

To be able to compare our results with Kelly et al. [31], we use the same approach to capture recent cyber attacks. The T-Pot solution, a mixture of Telekom and Honeypot, stands out with their sheer quantity of various honeypots. It requires 8 GB RAM and a minimum of 128 GB hard drive storage. Based on a Debian 10 Buster distribution, it relies on Docker to run their services [17]. T-Pot has to be deployed in a reachable network where intruders are expected. Either TCP and UDP traffic are forwarded without filtering to the network interface, or run it behind a firewall with forwarding rules. Specified ports for attackers are 1-64000, higher ports are reserved for trusted IPs, thus, a reverse proxy checks basic authentication. All daemons and tools run on the same network interface whereas some of them are encapsulated in their own Docker network. Docker is a lightweight virtualization technology that uses containers to run on the host system. More to docker... Figure 3.1 visualizes the technical concept of T-Pot. Each service has dedicated ports or port ranges that are exposed. Attackers can send TCP or UDP packets. ...More about the technical concept. In addition, T-Pot features different services types, namely (i) standard, (ii) sensor, (iii) industrial, (iv) collector, (v) next generation, and (vi) medical. Each service type features a different set of honeypots and tools tailored to their core idea. T-Pot feeds their data to an external Telekom service, however, this data submission can be turned off. For this chapter we restrict ourself to the latest version 20.06.0. Newer versions might be available by time and could differ from ours.

Honeypots and Tools

T-Pot combines honeypots with several tools to get a deeper inside of attackers. Followingly, all available components will be explained, albeit the sheer quantity of it. In addition, Table 3.2 gives a quick overview of all available honeypots in conjunction with (i) the port they are running on, (ii) what service type they are, (iii) what kind of interaction level, and (iv) a short decription.

ADBHoney [16] is a low interaction Android Debug Bridge (ADB) honeypot over TCP/IP. The importance of it lies in the ADB protocol that is used to debug and push content to the device. However, unlike USB it does not support any kind of ample mechanisms of authentication and protection. By exposing the ADB service

over any port, an adversary could connect and exploit it. ADBHoney is designed to catch malware that has been pushed onto devices.

Cisco Adaptive Security Appliance (ASA) [44] is a low interaction honeypot that detects CVE-2018-0101[5]. It is a vulnerability that could allow an unauthenticated, remote attacker to cause a reload of the affected system or to remotely execute code. This can be achieved by flooding a webvpn-configured interface with crafted XML packets. Consequently, the attacker obtain full control by executing arbitrary code.

Citrix Application Delivery Controller (ADC) honeypot [27] detects and logs CVE-2019-19781[6] scans and exploitation attempts. This vulnerability allows adversaries to perform directory traversal attacks. Files are accessible by path strings to denote the file or directory. In addition, some file systems include special character to easily traverse the hierarchy. Attackers take advantage of it by combining special characters in order to get access to restricted areas. [22]

Conpot [45] is a low interaction industrial honeypot for Industrial control systems (ICS), and Supervisory Control and Data Acquisition (SCADA). It provides a variety of different common industrial control protocols. An adversary should be tricked by the complex infrastructure, and lure him into attacks. In addition, a custom human machine interface can be connected to increase the attack surface. By randomly delaying the response time, conpot tries to emulate a real machine handling a certain amount of load.

Cowrie [38] is a medium to high interaction SSH and Telnet honeypot. It offers to log brute-force attacks and shell interactions with attacker. In medium interaction mode cowrie emulates a UNIX shell in Python, whereas in high interaction mode it proxies all commands to another system.

DDoSPot [7] is a low interaction honeypot to log and detect UDP-based Distributed Denial of Service (DDoS) attacks. It is used as a platform to support various plugins for different honeypot services, and servers. Currently, it supports DNS, NTP, SSDP, CHARGEN, and random/mock UDP server.

Dicompot [32] is a low interaction honeypot for the Digital Imaging and Communications in Medicine (DICOM) protocol. As other honeypots before, it mocks a DICOM server in Go to collect logs and detect attacks.

Dionaea [8] is a medium interaction honeypot that tries to capture malware copies by exposing services. It supports a vast variety of protocols such as FTP, SMB, and HTTP. Several modules can be integrated to work with Dionaea such as VirusTotal for further malware results.

Elasticpot [12] is a low interaction honeypot for elasticsearch, a search engine based on the Lucene library.

Endlesssh [60] is a SSH server that sends an endless, random SSH banner. The key idea is to lock up SSH clients that try to connect to the SSH server. It lowers the transaction speed by intentionally inserting delays. Due to connection establishing before cryptographic exchange, this module does not require any cryptographic libraries.

Glutton [46] is a generic low interaction honeypot that works as a MitM for SSH and TCP. However, lacking documentation does not provide a deeper inside of this honeypot.

Heralding [58] is a credential catching honeypot for protocols like FTP, Telnet, SSH, HTTP, or IMAP.

HellPot [28] is a “endless honeypot”. Connecting to this honeypot results in a memory overflow. Its key idea is to send an endless stream of data to the attacker until its memory, or storage runs out.

HoneyPy [24] is a low to medium interaction honeypot that supports several protocols such as UDP, or TCP. New protocols can be added by writing a custom plugin for it. HoneyPy should give the freedom of easily deploying and extending honeypots.

HoneySAP [24] is a low interaction honeypot tailored for SAP services.

HoneyTrap [61] is a low interaction honeypot network security tool. As stated by Werner [61], HoneyTrap is vulnerable to buffer overflow attacks.

IPPHoney [13] is a low interaction Internet Printing Protocol (IPP) honeypot.

Mailoney is a low interaction SMTP honeypot written in Python.

MEDpot [49] is a low interaction honeypot focused on Fast Healthcare Interoperability Resources (FHIR). It is a standard description data format to transfer and exchange medical health records.

RDPY [41] is a low interaction honeypot of the Microsoft Remote Desktop Protocol (RDP) written in Python. It features client and server side, and it is based on the event driven network engine Twisted. It supports authentication over SSL and NLA.

RedisHoneyPot is a high interaction honeypot for Redis protocol written in Go.

SNARE [47] is an abbreviation for Super Next generation Advanced Reactive honeypot. It is a successor of Glastopf, a web application sensor. In addition, it supports the feature of converting existing webpages into attack surfaces.

TANNER [48] can be seen as SNARE’s brain. Whenever a request has been sent to SNARE, TANNER decides how the response should like.

In addition, T-Pot integrates following tools to investigate and handle network traffic:

Table 3.2: Overview of all available honeypots of T-Pot in conjunction with the service type, interaction level, port, and a short description.

Honeypot	Description	Port
adbhoney [16]		
ciscoasa [44]		
citrixhoneypot [27]		
conpot [45]		
cowrie [38]		
ddospot [7]
